Abstract. In this paper, we study the fundamental trade-off between delay-constrained primary and secondary users in cognitive radio networks. In particular, we characterize and optimize the trade-off between the secondary user (SU) effective capacity and the primary user (PU) average packet delay. Towards this objective, we employ Markov chain models to quantify the SU effective capacity and average packet delay in the PU queue. Afterwards, we formulate two constrained optimization problems to maximize the SU effective capacity subject to an average PU delay constraint. In the first problem, we use the spectrum sensing energy detection threshold as the optimization variable. In the second problem, we extend the problem and optimize also over the transmission powers of the SU. Interestingly, these complex non-linear problems are proven to be quasi-convex and, hence, can be solved efficiently using standard optimization tools. The numerical results reveal interesting insights about the optimal performance compared to the unconstrained PU delay baseline system.

Key words: Cognitive radios, effective capacity, delay constraints, optimization, quality of service (QoS).

1 Introduction

The rapid evolution and ubiquity of wireless connectivity, as well as the wide proliferation of smartphones and powerful hand-held devices, mandate the handling of a huge amount of data in applications such as wireless multimedia. These applications are characterized by high bandwidth requirements and relatively stringent delay constraints. The limited wireless spectrum presents a major challenge and adds to the complexity of the problem.

The concept of cognitive radios was originally introduced by J. Mitola III in 1999 as a paradigm shift due to the severe under-utilization of the spectrum in

This publication was made possible by NPRP 4-1034-2-385, NPRP 09-1168-2-455 and NPRP 5-782-2-322 from the Qatar National Research Fund (a member of Qatar Foundation). The statements made herein are solely the responsibility of the authors.
some bands [1]. Cognitive radios enable opportunistic, or secondary users (SUs), to share part of the spectrum with licensed spectrum owners, referred to as the primary users (PUs), and possibly coexist with them in some paradigms.

Striking a balance between improving the performance of the opportunistic SUs and maintaining QoS requirements for the PUs is crucial for cognitive radio systems. This is particularly true for PUs running multimedia applications with stringent QoS constraints, which are particularly sensitive to potential performance degradation caused by the SUs. A significant portion of research in the cognitive radios arena has focused on improving the ability of the SUs to communicate over their, inherently, unreliable links. This is achieved either through improvements in SU data encoding schemes, e.g., [2], [3] or by proper adaptation of the SU power and rate in response to the time-varying channel conditions to achieve SU QoS requirements, e.g., [4], [5], [6].

Physical-layer channel models cannot be easily linked to QoS metrics. Therefore, in [7], the notion of “Effective Capacity” was originally introduced to express the maximum constant arrival rate that can be supported by a given channel service process while satisfying a statistical QoS requirement as specified by the QoS exponent, $\theta$. The effective capacity may be thought of as the dual wireless concept to the “Effective Bandwidth” notion originally introduced in [8].

Applied to cognitive radio systems, the effective capacity has been employed to characterize the performance of the SU in [9]. The authors derived expressions for the effective capacity of the SU for combinations of, both, fixed and adaptive power and rate scenarios. To enhance the prediction of the PU channel state, the authors in [10] proposed a feedback model, where the SU leverages the overheard primary ARQ message and uses information gleaned from the PU feedback channel to improve its sensing. It was shown, analytically, and using simulations that such side information can potentially increase the effective capacity of the SU.

In essence, the scheme in [10] minimizes the probability of PU re-transmission failure. However, this does not automatically guarantee the PU’s ability to satisfy delay constraints. In this paper, we incorporate an explicit QoS constraint on the PU, namely an average delay constraint, which is more relevant to users engaged in interactive or multimedia sessions. Thus, in this paper our prime objective is to maximize the SU effective capacity under an average delay constraint on the PU packets.

Our main contribution in this paper is two-fold. First, we develop a mathematical model that incorporates delay constraints into the optimization of the primary users and secondary users performance in cognitive radio networks. Second, we formulate, establish quasi-convexity and efficiently solve two optimization problems for maximizing the SU effective capacity subject to a constraint on the PU average packet delay. Towards this objective, we analyze the Markov chain models capturing the SU channel sensing dynamics and the PU queue dynamics. Next, we formulate, assess complexity (establish quasi-convexity) and solve our first (basic) optimization problem which decides the optimal spectrum sensing energy detection threshold to maximize the effective capacity subject
to the average PU delay constraint. Afterwards, we generalize the problem to jointly optimize over the energy detection threshold along with the SU transmission powers, yielding superior performance. Finally, we solve the problems numerically and demonstrate promising performance results for plausible scenarios.

The rest of the paper is organized as follows. First, we introduce the system model, assumptions and secondary user channel access model in Section 2. Afterwards, the basic and generalized optimization problems are formulated, to maximize the SU effective capacity under an average PU delay constraint, and examined for convexity in Section 3. Performance results confirming the fundamental trade-off and the optimal solution are quantified under plausible scenarios in Section 4. Finally, conclusions are drawn and potential directions for future work are pointed out in Section 5.

2 System Model

We focus on a simple cognitive radio network with one PU and one SU for mathematical tractability of the proposed model. We consider a time slotted system with slots of equal duration, $T$ seconds. All channels are assumed to experience Rayleigh block fading where the channel remains constant over a time slot and changes independently from one slot to another. The PU queue has a Bernoulli packet arrival process with rate $0 \leq \lambda_p \leq 1$ per slot and the SU is assumed to be fully backlogged (always has a packet to transmit) at the beginning of each time slot.

We assume a hybrid (underlay/interweave) cognitive radio model as introduced in [11], whereby the SU senses the channel at the beginning of the slot for $N$ seconds, where $N < T$, in order to determine the mode of channel access, as in the interweave model. Subsequently, the SU accesses the channel with high power, $P_1$, if the primary user is idle. Otherwise, the SU accesses the channel with lower power $P_b < P_1$ and correspondingly lower rate (as in the underlay model). The discrete-time SU channel input-output relation in the $i^{th}$ symbol duration is given by

$$y(i) = \begin{cases} 
\text{PU idle} : & h_s(i)x(i) + n(i), \quad i = 1, 2, \ldots \\
\text{PU active} : & h_s(i)x(i) + s_p(i) + n(i), \quad i = 1, 2, \ldots,
\end{cases}$$

where $x(i)$ is the complex channel input, $y(i)$ denotes the complex channel output and $h_s(i)$ is the channel fading coefficient between the secondary transmitter and receiver and $|h_s(i)|^2 = z_s(i)$. The primary transmitted signal, as perceived by the secondary receiver, is denoted $s_p(i)$, and $n(i)$ denotes the additive white Gaussian noise at the secondary receiver, with zero mean and variance of $\sigma_n^2$.

We adopt a simple energy detection spectrum sensing mechanism whereby the RF energy measured at the secondary transmitter is compared to an energy detection threshold, $\eta$, to decide whether the PU is active or idle. The channel sensing problem is typically modeled as a binary hypothesis testing problem [12]. Under these assumptions, the optimal Neyman-Pearson detector is [9]:

$$\begin{cases} 
\text{PU active} & \text{if } E[y(i)] > \eta \\
\text{PU idle} & \text{if } E[y(i)] \leq \eta
\end{cases}$$
\[ Y = \frac{1}{NB} \sum_{i=0}^{NB} |y(i)|^2 \leq_{H_1} \eta, \]  

(2)

where \( NB \) denotes the number of complex symbols in the \( N \) (in seconds) sensing duration with \( B \) (in Hz) being the channel bandwidth. The test statistic \( Y \) is chi-square distributed with \( 2NB \) degrees of freedom. In this case, the probability of detection can be derived as follows

\[ P_d = \text{Prob}\{Y > \eta | H_1\} = 1 - \frac{\gamma\left(\frac{NB\eta}{\sigma^2 + \sigma_{sp}^2}, NB\right)}{\Gamma(NB)}, \]  

(3)

where \( \gamma(x, s) \) is the lower incomplete gamma function, \( \Gamma(x) \) is the Gamma function and \( \sigma_{sp}^2 \) is the variance of \( s_p(i) \). The probability of false alarm can be written as follows

\[ P_f = \text{Prob}\{Y > \eta | H_0\} = 1 - \frac{\gamma\left(\frac{NB\eta}{\sigma^2}, NB\right)}{\Gamma(NB)}. \]  

(4)

2.1 The Secondary User Access Model

We employ a classic SU access model adopted earlier in the literature, e.g., [9,10], which is represented by the Markov chain in Fig. 1. The prime objective of this model is to capture the secondary user access decision and transmission parameters, namely, power and rate, depending on the spectrum sensing outcome and the instantaneous capacity of the secondary user channel. This is instrumental in characterizing the secondary user effective capacity for a statistical QoS constraint, \( \theta \), as shown later in the sequel. Thus, the secondary user transmission parameters have four cases, depending on the sensing outcome:

1. The PU channel is busy and the SU detects it as such: SU transmits with the lowest power \( P_b \) and rate \( r_b \).
2. The PU channel is idle while the SU detects it busy (false alarm (FA)): the SU sends its packet with power \( P_b \) and rate \( r_b \) as in case (1).
3. The PU channel is busy while the SU detects it idle (mis-detection (MD)): the SU sends with power \( P_i \) and rate \( r_i \), where \( P_i > P_b \) and \( r_i > r_b \).
4. The PU channel is idle and the SU detects it as such: the SU sends with power \( P_i \) and rate \( r_i \).

On the other hand, the secondary user channel has two states, OFF and ON, depending on whether the secondary user transmission rate exceeds the instantaneous channel capacity or not, respectively. This is caused by the time-varying fluctuations in the SU channel.

Next, we present the SU effective capacity (EC) subject to statistical QoS constraints. It has been originally established in [7] that the EC for a given QoS exponent, \( \theta \), is given by
Fig. 1: SU access and transmission model.

Fig. 2: A discrete-time Markov chain modeling the PU queue evolution.

\[ EC = - \lim_{t \to \infty} \frac{1}{t} \log_e \mathbb{E} \left\{ e^{-\theta S(t)} \right\} = - \frac{\Lambda(-\theta)}{\theta}, \quad (5) \]

where \( S(t) = \sum_{k=1}^{t} r(k) \) represents the time accumulated service process and \( \{r(k), k=1,2,\ldots\} \) is the discrete and ergodic stochastic service process.

For Markov modulated processes, like the model in Fig.1, it has been shown in [13] that the effective capacity can be reduced to

\[ EC = \frac{1}{\theta T B} \log_e (sp(\Phi(-\theta)R)), \quad (6) \]

where \( sp(.) \) denotes the spectral radius of a matrix, \( R \) represents the transition probability matrix of the secondary user Markov chain, \( T \) is the slot duration, \( B \) is the system bandwidth and \( \theta \) is the delay exponent. \( \Phi(\theta) = \text{diag}(\phi_1(\theta), \ldots, \phi_M(\theta)) \) is a diagonal matrix whose elements are the moment generating functions of the processes in the \( M \) states (\( M = 8 \) in our Markov chain model in Fig. 1).

2.2 Modeling the Primary User Queue

The primary user queue evolution is modeled formally by the discrete-time Markov chain shown in Fig. 2 with Bernoulli arrival rate \( \lambda_p \). The primary user service rate (i.e. queue length decreases by one), \( \mu_p \), depends only on two parameters, namely, the arrival rate and the primary channel outage probability, denoted \( \delta \), as follows,

\[ \mu_p = (1-\lambda_p)(1-\delta). \quad (7) \]

As the SU always uses the spectrum with different powers and rates depending on the PU activity, the primary channel outage may occur in two cases: first,
if the SU attempts to transmit on the PU channel with power $P_b$ and rate $r_b$, which in addition to the PU rate, $r$, brings the total rate on the channel above the instantaneous capacity. Alternatively, PU channel outage occurs when the SU attempts to transmit on the PU channel with power $P_i$ on a busy channel due to a mis-detection. Therefore, we can express the primary outage probability as follows:

$$\delta = P_d Pr\{z_p(i) < t_1\} + (1 - P_d) Pr\{z_p(i) < t_2\},$$

(8)

where $z_p(i) = |h_p(i)|^2$ and $h_p(i)$ is the fading coefficient of the PU transmission channel, $t_1 = \frac{2\pi - 1}{SINR_1}$ and $t_2 = \frac{2\pi - 1}{SINR_2}$. $SINR_1$ and $SINR_2$ denote the average signal to interference plus noise ratios for the PU in each outage case.

Solving the Markov chain in Fig. 2, which is an M/M/1 queue with steady-state probability of the PU queue having $i$ packets, $\pi_i$, and using simple queuing analysis (see [14]), the probability of PU empty queue, $\pi_0$, can be derived as

$$\pi_0 = \frac{\delta(\mu_p - \delta \lambda_p)}{\mu_p(1 + \delta) - \delta^2 \lambda_p},$$

(9)

and the utilization factor of the primary user queue, $\rho$, is

$$\rho = \frac{\delta \lambda_p}{\mu_p},$$

(10)

and, finally, the expected delay for the PU packets can be derived as [14]

$$D_p = \frac{\rho(\pi_0 - (1 - \rho)^2)}{\delta^2 \lambda_p(1 - \rho)^2}.$$

(11)

3 SU Effective Capacity Optimization Under PU Average Delay Constraint

In this section, we study the problem of balancing the conflicting QoS requirements for the primary and secondary users in cognitive radio networks. In particular, we seek to maximize the SU effective capacity (defined for a given statistical QoS exponent, $\theta$) subject to an average PU delay constraint, denoted $D_{max}$. Towards this objective, we formulate two optimization problems. The first (basic) problem solves for the optimum energy detection threshold, $\eta$, that maximizes the SU effective capacity subject to the aforementioned PU constraint. The key insight guiding the choice of the energy detection threshold, $\eta$, is that it affects the power level used by the SU which, in turn, affects the channel outage probability. For this reason, increasing $\eta$ always degrades the PU delay, yet, enhances the SU effective capacity up to some point beyond which it starts decreasing, as shown in Fig. 3. This is attributed to the fact that for very small $\eta$, the probability of false-alarm becomes higher and this results in a reduced SU effective capacity. On the other hand, for very large $\eta$, the SU will, with high probability, detect an idle channel, and will use high rate and power; hence, SU causes
higher interference to the PU; this results in the PU being active with a higher probability, therefore, a loss in the SU effective capacity.

Fig. 3 shows the SU effective capacity for different values of the sensing duration, $N$. We notice that the relation between effective capacity and energy threshold can always be divided into the two modes discussed above; one increasing and the other is monotonically decreasing/non-increasing. We also notice that if we increase $N$ from 0.002 sec to 0.005 sec, the SU effective capacity increases due to the more accurate estimate of the PU channel activity. On the other hand, when we increase $N$ beyond 0.005 sec, the SU effective capacity decreases because the slot portion dedicated to data transmission, $T - N$, decreases linearly with $N$.

3.1 Basic Problem Formulation

In this section, we maximize the SU effective capacity with respect to the spectrum sensing energy detection threshold, $\eta$, subject to the PU average delay constraint. Thus, the basic optimization problem can be formulated as

$$
\text{P1} : \max_{\eta} -\frac{1}{\theta TB} \log_e (s\phi(-\theta)R) \\
\text{s.t. } D_p \leq D_{\text{max}},
$$

where $D_{\text{max}}$ is the maximum allowable average PU delay which represents the predefined QoS for the PU. Next, we establish an important complexity reduction result for P1 which facilitates an efficient solution using standard optimization solvers.

**Theorem 1.** P1 is a quasi-convex problem in $\eta$.

**Proof.** In order to establish this result, we must assess the quasi-concavity of the SU effective capacity as well as the convexity of the delay constraint. We first establish the convexity of the constraint with respect to the optimization variable, $\eta$. From (8-11), the expected PU delay, $D_p$, is given by

$$
D_p = -\frac{1}{(1 - \lambda_p)(1 - \delta)} + \frac{(1 - \lambda_p)(1 - \delta)}{(1 - \lambda_p - \delta^2)(1 - \lambda_p - \delta)}.
$$
Since $D_p$ consists of two terms, it suffices to prove that each term is convex in $\eta$. This follows from the fact that the sum of convex functions is also convex. This can be validated by examining the Hessian of each term. Performing partial differentiation of each term with respect to $\delta$, then from (3) and (8), we get the partial derivative of $\delta$ in terms of $\eta$. The Hessian of the first term, denoted $f$, is given by:

$$f'' = \frac{q e^{-x}}{(1 - \delta)^2} x^{(NB-x)} (1 - NB - x),$$

(14)

where $x = \frac{\eta NB}{\sigma_n^2 + \sigma_p^2}$ and $q$ is a positive constant. It turns out from (14) that the Hessian is positive definite only under the following condition

$$\eta \leq (\sigma_n^2 + \sigma_p^2) \left(1 - \frac{1}{NB}\right).$$

(15)

For a stable system ($0 < \rho < 1$ and $0 \leq P_d \leq 1$), $\eta$ will never violate this condition and, hence, the first term of $D_p$ is convex over the optimization domain. Similarly, we can prove that the second term is also convex over the optimization domain, and, hence, the constraint in (12) is convex.

Second, we establish the quasi-concavity of the objective function, namely the SU effective capacity. To prove this, we must show that the function inside the logarithm (in (6)) is quasi-convex. This is based on the fact that if an arbitrary function $U$ is quasi-convex and a function $g$ is monotonically non-decreasing, then the function $f$ defined as $f(x) = g(U(x))$ is also quasi-convex [15]. Since the log function is non-decreasing, then it suffices to prove that its interior function is quasi-convex to establish the desired result. From (3), (4), (6) and ((28) in [9]), the objective function can be written as in (16) below where $z_s = |h_s|^2$ and $\alpha_1, \alpha_2, \alpha_3$ and $\alpha_4$ are the fading channel thresholds in case of no outage for the four SU sensing outcome cases stated in Section 2.1.

$$EC = \frac{-1}{\sigma_n^2 + \sigma_p^2} \log \left\{ e^{-\theta x} \left[ \rho (1 - \kappa_2) p(z_s > \alpha_1) + (1 - \rho) (1 - \kappa_1) p(z_s > \alpha_3) \right] + e^{-\theta x} \left[ \rho \kappa_2 p(z_s > \alpha_2) + (1 - \rho) \kappa_1 p(z_s > \alpha_4) \right] + (1 - \rho) \kappa_2 p(z_s < \alpha_2) + (1 - \rho) (1 - \kappa_1) p(z_s < \alpha_3) + (1 - \rho) \kappa_1 p(z_s < \alpha_4) \right\}$$

(16)

where $\kappa_1 = \gamma \left( \frac{nNB}{\sigma_n^2}, NB \right) / \Gamma(NB)$ and $\kappa_2 = \gamma \left( \frac{nNB}{\sigma_n^2 + \sigma_p^2}, NB \right) / \Gamma(NB)$. From (16), we have eight terms that can classified into three categories. First category takes the form

$$f_1 = q_1 (1 - \kappa_1),$$

(17)

the second category is of the form

$$f_2 = q_2 \rho = q_2 \frac{c_1 - c_2 P_d}{k_1 + k_2 P_d},$$

(18)

and, finally, the last category is of the form

$$f_3 = q_3 \rho P_d \quad \text{or} \quad f_3 = q_4 \rho P_f,$$

(19)
where \( q_1, q_2, c_1, c_2, k_1, k_2, q_3 \) and \( q_4 \) are positive constants. For the first category

\[
 f'_1 = q \left( e^{-\frac{NB}{\sigma_n^2}} \left( \frac{\eta B}{\alpha_n^2} \right)^{NB - \frac{2NB}{\sigma_n^2}} \left( 1 - NB - \frac{\eta B}{\alpha_n^2} \right) \right), \tag{20}
\]

which is convex only on the region indicated in (15), thus it is quasi-convex. Similarly, we can prove that all other terms are quasi-convex. Hence, their sum is also quasi-convex. Thus, the effective capacity is quasi-concave in \( \eta \) since it is the negative of a quasi-convex function.

### 3.2 The Generalized Optimization Problem

In this section, we generalize the basic problem \( \mathbf{P1} \) to optimize over the energy detection threshold, \( \eta \), along with the SU transmission powers, \( P_b \) and \( P_i \). As expected, the expanded policy space for the generalized problem yields noticeable performance improvement, as confirmed by the numerical results in Section 4, compared to the basic problem where the transmission powers are given and fixed throughout. Thus, the generalized optimization problem can be formulated as follows

\[
 \mathbf{P2} : \max_{\eta, P_b, P_i} -\frac{1}{\theta TB} \log_e(sP(\Phi(\theta)R))
\]

\[
s.t. \quad D_p \leq D_{\text{max}}
\]

\[
0 \leq P_i \leq P
\]

\[
0 \leq P_b \leq P,
\]

where \( P \) is the maximum SU transmission power. In preparation for our main result in this section, establishing the quasi-convexity of \( \mathbf{P2} \), we use the following two definitions from optimization theory.

**Definition 1** The Hessian of a multi-variate function \( f(x) \) is:

\[
 H_n(x) = \begin{bmatrix}
 f''(x)_{11} & \cdots & f''(x)_{1n} \\
 \vdots & \ddots & \vdots \\
 f''(x)_{n1} & \cdots & f''(x)_{nn}
\end{bmatrix},
\]

where \( f''(x)_{ij} = \frac{\partial^2 f}{\partial x_i \partial x_j} \). The function \( f(x) \) is convex if its Hessian \( H_n(x) \) satisfies \( H_n(x) \succeq 0 \) which means that the Hessian matrix is positive semi-definite.

**Definition 2** The bordered Hessian of a multi-variate function \( f(x) \), where \( x = (x_1, x_2, \ldots, x_n) \), is given by:

\[
 H^n_n(x) = \begin{bmatrix}
 0 & f'(x)_1 & \cdots & f'(x)_n \\
 f'(x)_1 & f''(x)_{11} & \cdots & f''(x)_{1n} \\
 \vdots & \vdots & \ddots & \vdots \\
 f'(x)_n & f''(x)_{n1} & \cdots & f''(x)_{nn}
\end{bmatrix},
\]

where \( f'(x)_i \) and \( f''(x)_{ij} \) denote the first and second partial derivatives, respectively.
where \( f'(x)_i = \frac{\partial f}{\partial x_i} \). If \( |H^b(x)| \leq 0 \) for all \( n \) and \( x \), then the function is quasi-convex (note that the condition that \( |H^b| \leq 0 \) is automatically satisfied).

**Theorem 2.** \( P_2 \) is a quasi-convex problem in the optimization variables \( \eta, P_b, P_i \).

**Proof.** For problem \( P_2 \), \( n = 3 \) as we have three optimization variables. We first start by establishing the convexity of the constraint with respect to the three optimization variables. Using (13) and (22), we can show that the delay constraint is convex and the other two constraints are affine in the optimization variables.

The only remaining step towards establishing the proof is to show the quasi-concavity of the objective function, \( EC \), with respect to the three optimization variables. This involves characterizing the determinants of the bordered Hessian of the \( EC \), defined in (23). Hence, from (23) and (16) we can simply show that \( |H^b_2| \leq 0 \) and \( |H^b_3| \leq 0 \) are satisfied and, hence, all terms are quasi-convex over the same domain*. Thus, the effective capacity is quasi-concave in \( \eta, P_b \) and \( P_i \) since it is the negative of a quasi-convex function.

4 Numerical Results

In this section, we present the numerical results which confirm the fundamental trade-off under investigation, between the secondary user effective capacity and the primary user average packet delay. Moreover, we characterize the optimal solution using standard optimization tools for convex problems, e.g., CVX [15]. The system parameters used throughout this section are as follows: \( r_b = 1.4 \) Mbps, \( r_i = 5.7 \) Mbps, \( P_b = 1 \) unit power, \( P_i = 3 \) unit power, \( B = 5 \) MHz, \( T = 0.1 \) sec, \( N = 0.002 \) sec, \( \lambda_p = 0.1 \), \( \sigma_n^2 = 10^{-4} \) and \( \theta = 0.02 \).

In Fig. 4, the effective capacity in (bit/sec/Hz) is plotted against the delay exponent, \( \theta \), for three different systems with \( \lambda_p = 0.1 \). The baseline system has no constraints on the average PU packet delay and, hence in essence, it represents the case where the PU queue is stable “primary stability constraint”. Thus, the baseline considers only maximizing the SU effective capacity which does not provide any delay guarantees for the PU. On the other hand, \( P_1 \) represents the optimal solution for the basic problem which optimizes only over the energy detection threshold, \( \eta \). \( P_2 \) represents the optimal solution for the generalized problem which optimizes over the three variables, \( \eta, P_b \) and \( P_i \). A number of key observations are now in order. First, it is straightforward to observe that the SU effective capacity monotonically decreases under the three systems as the delay exponent increases, i.e. the statistical delay constraint becomes stricter. Second, the baseline (unconstrained PU delay) system achieves the highest SU effective capacity, as expected. However, it is also worth noting that the performance loss, due to the finite PU delay constraint in \( P_1 \) and \( P_2 \) diminishes as the

* Details are omitted due to space limitations.
SU statistical delay constraint, represented by the delay exponent, $\theta$, becomes tighter. Third, we notice that the optimal solution for $P2$ outperforms that of $P1$ due to the expanded policy space under the generalized problem, $P2$. It is worth noting that, both, $P1$ and $P2$ are subject to a tight delay constraint on the PU average delay with $D_{max} = 0.057$ sec.

In Fig. 5, the effective capacity of the SU is plotted versus the primary user arrival rate, $\lambda_p$, for the three systems with $\theta = 0.02$. Clearly, the three systems start at the same point when $\lambda_p = 0$. As $\lambda_p$ increases, the unconstrained system (with no PU delay constraint) results in the highest SU effective capacity at the expense of increased PU delay. Also, $P2$ exhibits superior performance to $P1$ as optimizing over the transmission powers helps sustaining higher SU EC due to the expanded policy space.

5 Conclusions

In this paper we investigate a fundamental trade-off in delay-constrained cognitive radio networks. In particular, we characterize and optimize the trade-off between the secondary user effective capacity and the primary user average delay. Towards this objective, we employ Markov chain models to characterize the secondary user effective capacity and the average packet delay in the primary user queue. First, we formulate two constrained optimization problems to maximize the secondary user effective capacity subject to an average primary user delay constraint. Afterwards, the two formulated problems are proven to be quasi-convex and, hence, can be solved efficiently using standard techniques. Finally, the numerical results reveal interesting insights about the optimal performance compared to the unconstrained PU delay baseline system studied earlier in the literature.
